Mosaic Activating *RAS* Mutations in Nevus Sebaceus and Nevus Sebaceus Syndrome

Journal of Investigative Dermatology advance online publication, 25 October 2012; doi:10.1038/jid.2012.377

TO THE EDITOR

Nevus sebaceus is a common congenital skin hamartoma, classically appearing as a yellow-hued plaque on the scalp, face, or neck. It is the hallmark lesion of Schimmelpenning/nevus sebaceus syndrome (OMIM: 163200), a multisystem disorder that includes a spectrum of central nervous system, ocular, skeletal, and cardiovascular defects. Secondary neoplasms arise within nevus sebaceus at a modest but elevated rate (Moody *et al.*, 2012), prompting disagreement about whether they should be routinely excised (Shwayder, 2011). Determining the pathogenesis of nevus sebaceus would provide a framework to better understand this lesion and its associated syndrome.

The appearance of nevus sebaceus along Blaschko's lines suggests that a mosaic genetic mutation causes the lesion, with more extensive multisystem involvement potentially underlying the syndromic form (Happle, 1993). Here, we report a case of an individual with nevus sebaceus syndrome. As individuals with this syndrome are uncommon, we sought to identify associated mutations by comparing the exome sequence of the nevus sebaceus from our patient with those of sporadic nevus sebaceus.

Our index patient is a 38-year-old woman who was born with Chiari malformation, myelomeningocele, and resultant paraplegia. Because of hydrocephalus and marked ventricomegaly, she required ventriculo-peritoneal shunt placement. Imaging studies demonstrated rotoscoliosis. She has had cognitive developmental delay and suffered from generalized seizures during childhood. In her early thirties, she experienced a middle right cerebral artery stroke. Despite her condition, she remains high functioning and lives in an assisted care facility. No other family members are affected by similar medical conditions, and no cause has been attributed to her findings.

In the past year, the patient became bothered by growths on her forehead and presented to our clinic. On examination, frontal bossing was observed, as well as a yellow-hued papillomatous plaque on the paramidline forehead that had been present since birth (Figure 1a). Several pedunculated papules were noted within the lesion. No other significant cutaneous findings were appreciated.

As per patient request, the lesion was excised and a portion of the excision specimen was collected with her written informed consent. Our study complied with the Declaration of Helsinki Principles and was approved by the Stanford Institutional Review Board. Histological evaluation confirmed features of nevus sebaceus with no secondary neoplasms (Figure 1b). Accordingly, in light of the extensive neurological and skeletal involvement, a diagnosis of Schimmelpenning/nevus sebaceus syndrome was made. In efforts to determine an underlying genetic mutation, four additional, independent nevus sebaceus samples were collected from elective excisions along with adjacent normal skin controls. The five samples were subjected to exome sequencing and analyzed for mutations using Seqgene (Deng, 2011) and DNAnexus (http://www.dnanexus.com) as described in the Supplementary Material online.

Analysis of recurrent lesion-specific variants identified an *HRAS* point mutation (c.37G>C, p.Gly13Arg) in the index case and in two of four isolated

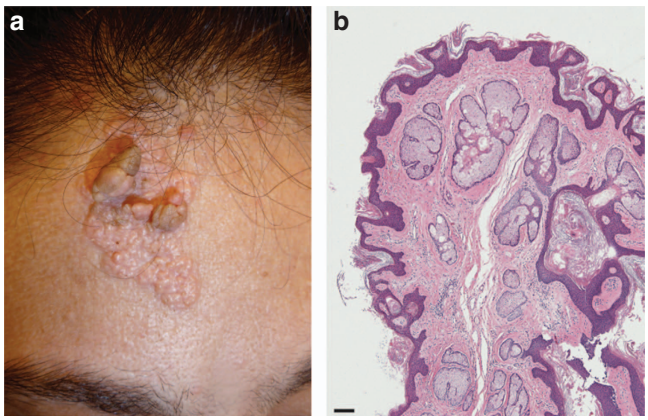

Figure 1. Clinical and histological features of a patient with nevus sebaceus syndrome. (**a**) A yellow-hued, papillomatous, oblong plaque on the paramidline forehead of the index patient. (**b**) Hematoxylin and eosin–stained section (original magnification × 40) of a pedunculated papule from the patient's lesion showing epidermal acanthosis, papillomatosis, the absence of hair follicles, and ectopic sebaceous glands opening directly to the epidermal surface. Bar = 100 μm.

Abbreviations: MAPK, mitogen-activated protein kinase; pERK, phosphorylated ERK

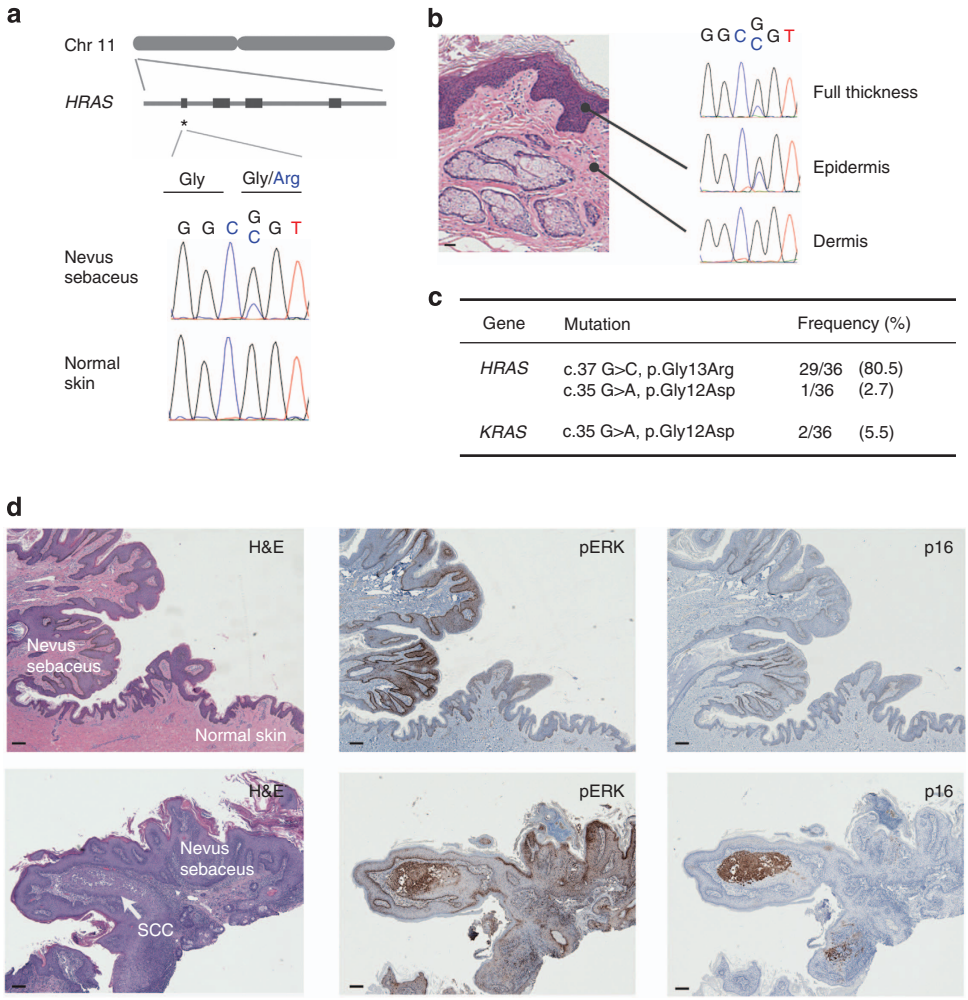

Figure 2. Activating mosaic *RAS* mutations in nevus sebaceus. (**a**) Genomic localization of *HRAS* to the short arm of chromosome 11 and schematic of its gene structure. A prominent mutational hotspot in coding exon 1 (codons 12–13) is marked with an asterisk. Sanger sequencing confirms a c.37 G>C, p.Gly13Arg mutation specific to lesional tissue. (**b**) Laser capture microdissection of the epidermis and dermis of nevus sebaceus demonstrates the presence of the *HRAS* mutation exclusively in the epidermis. (**c**) Summary of *RAS* mutations identified in nevus sebaceus. (**d**) The activated RAS/mitogen-activated protein kinase (MAPK) pathway in nevus sebaceus. Upper row: nevus sebaceus transitioning into normal skin. Immunohistochemical staining for phosphorylated ERK (pERK), a downstream effector of the *RAS* pathway, is increased in nevus sebaceus compared with adjacent normal skin. Staining for p16 is homogenously negative. Lower row: an early focus of squamous cell carcinoma (SCC) arising within a nevus sebaceus. This area is characterized by stronger pERK signal and distinct p16 enrichment. All original magnifications are at ×40. Bar = 100 μm. H&E, hematoxylin and eosin.

nevus sebaceus samples, with a variant allele frequency ranging from 17 to 43%. Sanger sequencing confirmed the *HRAS* mutation in all five lesional samples and its absence in all matched controls (Figure 2a). Examination of the two *HRAS* mutation–negative exomes showed low sequence coverage (<20 reads) at the mutation site, which may account for the false-negative calls.

Lesions arising along Blaschko's lines are hypothesized to stem from a mosaic mutation affecting a specific cell lineage during development. To evaluate whether the candidate mutation fits this criterion, we used laser capture microdissection to isolate DNA from the lesional epidermis and dermis from the index case and one of the sporadic nevus sebaceus samples. In both cases, the mutation was limited to the epidermis, supporting the hypothesis of an acquired mutation affecting ectodermal precursors (Figure 2b). Both alleles were represented in approximately equal intensities, indicating that the mutation is likely heterozygous.

We next performed targeted Sanger sequencing on a validation set of 31 independent nevus sebaceus samples from archived tissues, and identified the *HRAS* p.Gly13Arg mutation in 24/31 samples and p.Gly12Asp in one sample. The remaining mutation-negative cases were evaluated for *KRAS* and *NRAS* hotspot mutations, identifying two samples carrying *KRAS* p.Gly12Asp mutations. Six validation samples had patient-matched normal skin tissue available, and the corresponding *RAS* mutations were absent in all six control samples. In total, 32 of 36 samples (89%) demonstrated *HRAS* or *KRAS* mutations, confirming a strong correlation between activating *RAS* mutations and nevus sebaceus (Figure 2c). We suspect that the remaining negative cases may be due to genetic heterogeneity, or

due to a low mutant allele frequency secondary to admixture with normal tissue.

RAS promotes cell growth through activation of multiple pathways, a main pathway being the mitogen-activated protein kinase (MAPK) signal-transduction pathway. Activating mutations in this gene family have well-established links to cancer (Schubbert *et al.*, 2007). Germline activating *HRAS* mutations cause Costello syndrome, which features predisposition to neoplasia and development of cutaneous papillomas (Gripp and Lin, 2012). Taken together, the known biological features of activated *RAS* genes are consistent with the hamartomatous overgrowth and elevated neoplasia risk observed in nevus sebaceus.

To evaluate *RAS*-MAPK signaling, we performed phosphorylated ERK (pERK) staining on a set of nevi with confirmed *HRAS* mutations. Immunohistochemistry revealed increased pERK staining in lesional versus normal epidermis, consistent with *RAS*-MAPK hyperactivation (Figure 2d). In one sample, a squamous cell carcinoma was identified arising from nevus sebaceus, highlighted by elevated p16 staining (Hodges and Smoller, 2002). The pattern of neoplasia arising from a background of upregulated pERK supports the hypothesis that *RAS*-MAPK hyperactivation may predispose toward the development of secondary neoplasms in nevus sebaceus.

Basal cell carcinomas were once thought to arise commonly from nevus sebaceus, but others have subsequently contended that the majority of these tumors are actually trichoblastomas (Cribier *et al.*, 2000). Our data provide genetic support for the latter opinion, as most basal cell carcinomas arise from Hedgehog pathway dysregulation and lack *RAS* mutations (Reifenberger *et al.*, 2005). Our findings also raise the possibility that tumors arising from nevus sebaceus, such as syringocystadenoma papilliferum and trichoblastomas, may be associated with *RAS* mutations as well.

Using targeted sequencing and SNaPshot assays, Groesser *et al.* (2012) and Hafner *et al.* (2012) have recently profiled oncogenic hotspot mutations in epidermal and sebaceus nevi. Together with the results presented here and by others in this issue (Levinsohn *et al.*, 2012), the cumulative data demonstrate that keratinocytic epidermal nevi and sebaceus nevi are both associated with activating *HRAS* p.Gly13Arg and *KRAS* p.Gly12Asp mutations, supporting the belief held by some clinicians that they represent a spectrum of the same entity (Sybert, 2010). We postulate that the phenotypic difference between these nevi may be related to the extent of the mutation, as well as body site–specific embryological patterns and environment. The knowledge of the genetic basis of nevus sebaceus and its associated syndrome represents a further step toward understanding genotype–phenotype correlations arising from genetic mosaicism.

CONFLICT OF INTEREST

The authors state no conflict of interest.

ACKNOWLEDGMENTS

We thank the patients and their families for taking part in this project. We also thank S Aasi, R Khosla, and P Lorenz for their valuable assistance.
